Abstract

The quantum effective action may be used to invert information from phenomena, either measured or ideal, to the microscopic Lagrangian. As an example of this procedure the lattice composition of a solid can be determined in principle from desired critical phenomena. Also, the engineering of scattering and optical properties of particular degrees of freedom, and excitations, in terms of the temperature and electro-magnetic fields may be performed.

Quantum field theory in general can be 'solved' in terms of the functional integration of the quantum fields. One recipe for doing this involves the integration of the propagating modes in perturbation theory; the perturbative aspect can be changed once the coupling dependence of series is obtained. A procedure for obtaining the full scattering, and the quantum effective action that generates it, is described in [1]-[3] (and references therein); scalar, gauge, and gravitational models are analyzed within the perturbative context in [1], [2] and classically in [5] and [6]. Further simplifications of the tensor algebra may be performed [4].

The quantum action of condensed matter models can also be obtained with the full dependence on the coupling constants, as a power series. The lattice type and composition is incorporated into the propagators and integration region (via the Brillouin zone, for example). For example, the action describing phonons and electrons in the non-relativistic limit can be obtained to all orders in the coupling and energy scales.

The quantum action as a function of the lattice Λ , the structure constants and properties of the cores f_i , non-linearities associated with the electrons and the band, the temperature T , and external fields E and B may be included into the determination of the quantum action. The microscopic coupling constants in the bare Lagrangian can be given their full perturbative series.

The effective action in the condensed matter context takes on the form,

$$\psi\Delta(x;T,\Lambda)\psi + m\psi\psi + F_{\text{phonon}}^2 + F_{\text{e.m.}}^2. \quad (1)$$

together with the interactions,

$$\prod \psi\psi \dots \psi A_p \dots A_p A_{\text{e.m.}} \dots A_{\text{e.m.}} \quad (2)$$

combined with the derivatives placed in physically allowed places, which are derived from the fundamental theory. The bare theory could also include the electromagnetic interactions derived from the atomic cores, and the non-linearities associated with the phonon displacements (i.e. quartic and higher order terms).

The quantization of the bare theory should take into account the Brillouin zone features in the k -space integration. Within the derivative expansion, this integration change does not alter the complications with the integrals.

The application of the quantization, or mode expansion in the classical and quantum regime, generates the coefficients of the terms in (2) in momentum space. These coefficients,

$$f_{s_{ij};f_i,\Lambda,T;g_j} \tag{3}$$

are expansions in the lattice structure Λ , f_i and the coupling constants g_j . The latter model the electron, phonon, and electromagnetic effects; they could also represent the core potentials of the atoms and non-linearities associated with the lattice. These functions are computable within the derivative expansion to any order once the bare Lagrangian is specified. (A momentum representation could be used to formulate the interaction potential from the cores in the lattice. The temperature dependence is also included in the bare theory.)

The integral representations in [1]-[2] can be used to find the full effective action and the coefficients $f_{s_{ij};f_i,\Lambda,T;g_j}$ as power series. All couplings f_i , Λ , g_i and the temperature T can be left as arbitrary parameters in the bare theory. The phonon (and other modes) populations at a given temperature can be inserted as background fields.

The point of this calculation is that with the arbitrariness of these parameters, the functions f multiplying the effective action's terms can be used to deduce the parameters. In a quantum field theory form, or at a point at criticality in the lattice model, this inversion is clear from the power series form in the coupling as computed in [1]-[6].

It would be useful to compute the entire effective action as a function of all of these bare interactions, and to produce a computational program to carry out the inversion. This would enable a reverse modeling, that is, to model desired phenomena even at non-criticality, to the bare Lagrangian including the construction of the lattice and its constituents. This program is technically straightforward to carry out in practice, without complications in principle. The full effective action is available via the summation of Feynman diagrams, or those in the derivative expansion. The inversion of the functions $f_{s_{ij};\Lambda,T,g_i}$ to the couplings and lattice involve polynomial and transcendental equation solutions. However, in principle, any desired phenomena at or near criticality can be obtained with enough self-consistent information from the couplings and lattice.

The band electron band information can be obtained from the low-energy effective action, including the quantum propagator. Associated information from an external

photon field can be used further to turn on background couplings and change further these functions f by including the $\langle A_{\text{e.m.}} \dots A_{\text{e.m.}} \rangle$. The momentum dependence (or frequency bandwidth and amplitude) of the external field $A_{\text{e.m.}}$ can be used in theory to alter a near infinite number of terms, depending on the precision and accuracy of the waveform. These feature of the background electromagnetic field can be used to alter substantially the band structure of the electrons and the Fermi filling (after including possible interactions with the lattice cores).

The inversion of the effective action can be done with the background fields to obtain a variety of phenomena. Even seemingly complicated lattices, such as the cuprates, can be modeled in a straightforward fashion, once the bare Lagrangian is produced. Bandwidth absorption and reflection can be produced as a function of desired properties, and collective phenomena can be made after the appropriate field redefinitions. Specified quantum effects can be tuned for.

A computational (e.g. computer program) can be made that tunes phenomena to specified materials. For example, the band structure, optical properties, electron scattering, criticality involving temperature, and collective phenomena can be inputs and the lattice structure and external fields could be outputs. This is direct to implement using the full effective action, if accurate from the bare Lagrangian and its interactions. An arbitrary number of interactions can be used in the bare theory, without much complication from a computational perspective including quantum effects.

In principle, desired phenomena can be obtained from the lattice and the external fields (involving derivatives); in practice there are technical obstacles. It is markable that the desired phenomena can be turned into the microscopic data, at bandwidth involving phase transitions at room temperature once the interaction $f_{s_{ij};\Lambda,g_i,T}$ functions are tunable, which is possible with the effective action. Amorphous materials with the appropriate bare lattice and core interactions are also available.

Note Added: A computer program is being developed to compute large orders in the scattering and effective action. This program should have obvious importance to both theory and industry.
